Introduction
When confronted with the term clean steel, my friend – who is an expert in minerals processing – conjures up images of washing his car. Although, in pyrometallurgical terms, steel cleanliness affects the body of his car, clean steel production does not include soapy water. This paper presents an overview of what clean steel means to a pyrometallurgist, as well as an explanation of its relevance to South Africa.

(Very) simplistic process overview

Car manufacturing
In car manufacturing, the mass of the steel body structure typically ranges between 200 and 400 kg (WorldAutoSteel, 2013). Hydroforming is the manufacturing process used to convert a sheet of steel into the panel of a car door or other shape required (Singh, 2003). In a typical hydroforming process cycle, the sheet metal blank is placed onto the lower tool, the die is closed, and fluid pressure applied to one side of the blank. The pressure is sufficient to cause the blank to deform plastically and take the shape of the tool cavity (Singh, 2003). During plastic deformation, nonmetallic inclusions will cause the steel to deform. Typical nonmetallic inclusions are Al_{2}O_{3} as a product of deoxidation – explained later on – and a solid solution of the spinel MgAl_{2}O_{4} and Al_{2}O_{3} (Pistorius, Verma, and Fruehan, 2014). These inclusions form during the steelmaking process.

Iron ore
In iron ore, iron (Fe) is present in an oxidized state as Fe^{3+} in haematite (Fe_{2}O_{3}) or a combination of Fe^{2+} and Fe^{3+} in magnetite (Fe_{3}O_{4}) (Poveromo, 1999). To produce steel, the oxygen is removed from the Fe in order to reduce its oxidation state to zero, Fe^{0}. In pyrometallurgical processing the principles of chemistry are applied to achieve this objective.

Ironmaking
To reduce the oxidation state of Fe, the iron ore is contacted with a reagent that has a greater affinity for oxygen. In commercial ironmaking, carbon (C) is used to achieve this objective (Sundholm et al., 1999) as oxygen (O) has a higher affinity for C than for Fe under certain conditions. These conditions are governed by the rules of thermodynamics (Turkdogan and Fruehan, 1999). According to the Oxford Dictionary (Oxford University Press, n.d.), pyrometallurgy is the branch of science and technology concerned with the use of high temperatures to extract and purify metals. Therefore, in pyrometallurgy, processing temperature is one of the parameters manipulated to exploit the rules of thermodynamics.

Carbon, when used to reduce the oxidation state of the Fe, is referred to as the reducing agent (Sundholm et al., 1999). C reacts with the O associated with the Fe when the C is present as solid carbon, as carbon dissolved in a metal phase, or as carbon present in a gaseous phase as carbon monoxide (CO) gas (Burgo, 1999; Turkdogan and Fruehan, 1999). Different technologies are available (Feinman, 1999) to exploit these reactions, with the blast furnace being the main technology (Burgo, 1999). The liquid pig iron tapped from the
Introduction to the production of clean steel

blast furnace is saturated in C, with typical contents of 3.5% to 4.4% (Burgo, 1999). Unfortunately, iron ores contain not only Fe but also other elements, all present at higher oxidation states in the form of minerals. These elements include silicon (Si), manganese (Mn), phosphorus (P), aluminium (Al), magnesium (Mg), calcium (Ca), titanium (Ti), potassium (K), sodium (Na), and sulphur (S) (Burgo, 1999; Poveromo, 1999). During the ironmaking process, the oxidation states of some of these elements – especially Si, Mn, and P – are reduced to zero as well. Apart from Fe and C, the liquid pig iron tapped from a blast furnace therefore also contains Si (1.5%), Mn (1.0–2.0%) and P (<0.4%) as major components (Burgo, 1999).

In ironmaking, coal and anthracite, or products derived from them, are used as sources of C (Sundholm et al., 1999). As in the case of iron ores, the coal and anthracite contain not only carbon, but also other elements in the form of gangue minerals – most importantly S. This S, together with the S present in the iron ore, will report to the slag phase, resulting in S contents of 0.05% or less, typical for liquid pig iron tapped from a blast furnace (Burgo, 1999).

Steelmaking

To produce steel suitable for car body manufacturing, the liquid pig iron tapped from a blast furnace has to be refined to reduce the C, Si, Mn, S, and P content.

In the first refining step, O2 gas is blown under controlled conditions into the liquid pig iron, where it reacts preferentially with C, Si, and Mn (Fruehan, 1998), increasing their oxidation states from zero to C2+ or C4+ as CO or CO2 gas, and to Si4+ as SiO2, and Mn2+ as MnO, both of the latter reporting to a liquid slag phase. By controlling temperature and slag chemistry, P is also oxidized from zero to a higher oxidation state, and S to S2+ by forming CaS, both reporting to the slag phase (Miller et al., 1998). As with ironmaking, different steelmaking technologies are available (Fruehan and Nassaralla, 1998; Jones, Bowman, and Lefrank, 1998; Miller et al., 1998) to exploit these reactions, with the basic oxygen furnace (BOF) being widely applied in the treatment of liquid pig iron (Miller et al., 1998).

During tapping of the BOF, the refined steel is separated from the slag. After O2 blowing, the dissolved O content of the steel is too high for casting purposes and has to be reduced. This reduction is achieved by adding Al or Si, which react with the dissolved O to form Al2O3 or SiO2 (Kor and Glaws, 1998). Under ideal conditions the reaction products report to the slag phase. Under non-ideal conditions, the reaction products remain in the steel as nonmetallic inclusions. Therefore, steel producers actively manage the inclusion content and morphology of their products through the introduction of Ca additions and soft purging with Ar gas. The treatment of the steel described here occurs in the ladle furnace (LF) (Kor and Glaws, 1998). Treatment in the LF also includes further reduction of the S content of the steel through synthetic slag additions as well as final adjustments to the chemical composition of the steel (Kor and Glaws, 1998).

During tapping of the steel from the primary vessel (typically a BOF) or arcing at the ladle furnace, nitrogen (N) in the air dissolves into the steel. Many of the alloys and synthetic slag components added to the steel at the ladle furnace contain water, which has the potential to increase the dissolved hydrogen (H) content of the steel. In many instances the levels of these gases have to be reduced with vacuum oxygen degassing (VOD) technology – one of the technologies available (Kor and Glaws, 1998). VOD technology is also used to reduce the carbon content of ultra-low carbon steel grades (Kor and Glaws, 1998).

Summary

Figure 1 presents a summary of the iron- and steelmaking processes.

Iron- and steelmaking technologies applied in South Africa

In South Africa, iron and steel are produced at a number of steelmaking plants (Jones, n.d.) using various technologies. ArcelorMittal South Africa operates four steelworks named after the towns they are based in. EVRAZ Highveld Steel is based in Emalahleni, and Columbus Stainless in Middelburg; SCAW Metals operates a steelworks in Germiston, Cape Gate in Vanderbijlpark, and SA Steelmakers in Cape Town (Delport, 2014).

Figure 1 – A very simplistic overview of clean steel production
The largest integrated steel plant is the ArcelorMittal South Africa Vanderbijlpark Works (ArcelorMittal, n.d.-a). The Vanderbijlpark Works utilizes blast furnaces for the production of pig iron and rotary kilns for the production of direct reduced iron (DRI) – a product in the solid state (ArcelorMittal, n.d.-b). Both pig iron and DRI are produced from a combination of lumpy iron ore and sintered ore fines. Basic oxygen furnaces (BOFs) are applied for the production of primary steel. The electric arc furnaces (EAFs) were decommissioned in 2012 (Mathews, 2012). Secondary steelmaking is conducted in ladle furnaces, followed by degassing in either a Ruhrsthal Heraeus (RH) degasser or vacuum arc degasser (VAD).

ArcelorMittal South Africa operates three other plants (ArcelorMittal, n.d.-b): Saldanha Works, Newcastle Works, and Vereeniging Works. The process flow sheet and technologies applied at Saldanha Steel are discussed in the next section in more detail. At the Newcastle Works, iron is made from lumpy and sintered iron ore in a blast furnace. BOF technology is used for primary steelmaking, and ladle furnace and RH degasser technologies for secondary steelmaking. The Vereeniging Works does not have an ironmaking facility. During the primary steelmaking step, scrap is melted in EAFs. Secondary steelmaking technologies applied are the ladle furnace and vacuum degassing.

At EVRAZ Highveld Steel, iron is made using a combination of rotary kilns for solid-state reduction and open-bath furnaces for final reduction and melting (Steinberg, Geyser, and Nell, 2011). The choice of technology was driven by the high levels of titania (TiO$_2$) present in the magnetite ore. As the pig iron tapped from the open-bath furnaces contains high levels of vanadium, primary steelmaking is conducted in two steps: a soft oxygen blow at the shaking ladles to remove the vanadium, followed by treatment in BOFs. Ladle furnace technology is the only secondary steelmaking technology applied.

The only facility for the production of stainless steel in South Africa is Columbus Stainless, which uses EAF technology to melt recycled steel scrap together with metal alloys containing Cr and Ni, and an argon-oxygen decarburizer (AOD) for refining (Columbus Stainless, n.d.). No secondary steelmaking technologies are described.

Production of clean steel at Saldanha Steel

ArcelorMittal Saldanha Works was commissioned in 1998, with a unique combination of production units (Figure 2).

A Corex unit produces hot metal, and the surplus gas is fed into a Midrex unit that produces DRI. Both products are fed into a twin-shell Conarc furnace, which is a hybrid EAF/BOF. The steel is then treated in a ladle furnace where final chemical adjustments are made before being sent to a thin slab caster (TSC). Slab temperatures are equalized in a roller hearth furnace (RHF) where surplus gas from the ironmaking units is burned. In a seven-stand hot strip mill (HSM), the slabs are reduced to their final thickness, mainly ≤1.5 mm. A temper mill (TM) improves the flatness of the strip, and a packaging unit puts strapping around it for shipment to customers mainly in East and West Africa.

The Corex unit produces hot metal in a configuration of a split blast furnace. In the bottom section, the melter-gasifier, coal and coke are gasified with 95% pure O$_2$ to form CO gas and energy. The gas is fed upwards into the second section, a shaft pre-loaded with iron ore, iron pellets, and coke moving downward. The gas strips the extra oxygen from the iron ore, and the metallized pellets gravitate into the high-temperature zone of the melter where they are further reduced and melted. In the process, some C, Si, P, and S from the coal goes into solution into the molten iron. Most of the SiO$_2$ and Al$_2$O$_3$ from the coal is removed by the lime and dolomite added to make a fluid slag.

The excess gas is cleaned by a wet scrubber, and the CO$_2$ is removed by vacuum pressure swing adsorption (VPSA).
Introduction to the production of clean steel

The gas is then heated and passed into a shaft containing iron ore and pellets, similar to that of the Corex unit. Here the oxygen is more thoroughly stripped by the gas, resulting in >90% metallization (typically 90–92%), and DRI is produced. All impurities from the ore and pellets remain in the DRI. The DRI is cooled by injection of liquefied petroleum gas (LPG), a mixture of propane and butane, which ‘cracks’ and deposits carbon on the DRI.

The hot metal can then be desulfurized by the addition of calcium carbide (CaC₂), which combines with the S dissolved in the hot metal to form CaS in a slag on top of the ladle. From here the hot metal is charged into one of the twin shells of the Conarc. The name is derived from ‘converter and arc furnace’. In converters, steel is produced from hot metal by the injection of oxygen via a top lance. In an arc furnace, steel scrap and DRI are melted using electrical energy delivered by carbon electrodes.

The Conarc at Saldanha Works consists of two refractory-lined vessels that share one oxygen top lance and one electrode gantry between them. In the first step, oxygen is delivered by carbon electrodes.

Table I summarizes the typical chemical compositions and temperatures of the hot metal and steel at the different production stages.

**School on production of clean steel**

The Center for Iron and Steelmaking Research at Carnegie Mellon University (CMU) in Pittsburgh, Pennsylvania, USA has a proud history in iron- and steelmaking. Collaboration between CMU and the South African iron and steel industry.

The Journal of The Southern African Institute of Mining and Metallurgy

560 JUNE 2015 VOLUME 115
Introduction to the production of clean steel

has included a school on steelmaking presented by Professor Richard Fruehan in Vanderbijlpark in 1996. Professor Chris Pistorius from the University of Pretoria joined Professor Fruehan in 2008 and is now the POSCO Professor of Iron and Steelmaking in the Department of Materials Science and Engineering at CMU.

Professor Pistorius continues the collaboration between CMU and the South African iron and steel industry by addressing a number of topics under the headings ‘controlling dissolved elements’ and ‘controlling micro-inclusions’. The work done by Professor Pistorius describes the relevant process conditions (temperatures, oxygen activity, slag basicity, stirring) in the blast furnace, steelmaking converter, EAF, ladle furnace, and caster; and investigates ways in which dissolved elements are controlled both on a theoretical and on a practical level. On the topic of micro-inclusions, Professor Pistorius has examined the principles of control, sources of micro-inclusions, and techniques used to assess micro-inclusions.

A future ‘Clean Steel’ event would not only benefit South African steel producers, but also allow suppliers of raw materials and consumables to obtain a better understanding of their clients’ perspectives on iron- and steelmaking; and inform downstream consumers of the challenges faced by their suppliers.

Conclusions

The conversion of iron ore to steel requires several processing steps. For each processing step, different types of technologies are available and applied in South Africa. The plant at Saldanha Steel is an example of an integrated mini-mill that produces steel from iron ore.

For a pyrometallurgist producing steel, the term clean steel refers to the control of the dissolved elements and the nonmetallic inclusions in the steel. A school focusing on the principles of control, sources of micro-inclusions, and techniques used to assess micro-inclusions.

A future ‘Clean Steel’ event would not only benefit South African steel producers, but also allow suppliers of raw materials and consumables to obtain a better understanding of their clients’ perspectives on iron- and steelmaking; and inform downstream consumers of the challenges faced by their suppliers.
